---

1 Streaming Algorithms

We now move from sublinear time algorithms to the related area of streaming algorithms. These algorithms are another family of sublinear algorithms but instead of time as in sublinear time algorithms, they focus on space of algorithms. A streaming algorithm processes its inputs in small chunks, one at a time, and thus does not need to store the entire input in one place. For motivation, consider a router in a network: the router needs to process a massive number of packets using a limited memory much smaller than what allows for storing all the packets it sees during its process.

In the following, we give a (semi) formal definition of the model and a simple example of a streaming algorithm. We then switch to considering one of the first problems considered in the streaming model, the distinct element problem, and design a streaming algorithm for that.

1.1 The Streaming Model of Computation

We now define the model formally. The input consists of \( n \) elements \( e_1, e_2, \ldots, e_n \), where each \( e_i \) belongs to some universe \( \mathcal{U} \), that are received one at a time by the algorithm, sequentially. Every time a new element is received, the previous one is erased, so the algorithm only has access to the most recent element. The algorithm has a local memory available, separate from the input, which is (ideally) much smaller than the input (and so we cannot store the input entirely by the end of the stream).
The goal in this model is to design algorithms that use only a small amount of memory compared to the input size, typically (but not always) of size poly(log n, log |U|) bits.

1.2 Warm-Up: Uniform Sampling in a Stream

Let us start with the following simple problem.

Problem 1. Given a stream of elements from the universe [m], sample an element $e_i$ uniformly at random.

If we know the length $n$ of the input in advance, this is trivial – simply sample a number $i \in [n]$, keep a counter of the number of elements seen so far, and store the $i$-th element. This algorithm uses $O(\log n + \log m)$ bits of space: $O(\log n)$ for the index $i$ and the counter, and $O(\log m)$ for the element. But what if we do not know the length $n$ of the stream? The following Reservoir Sampling algorithm solves this problem.

Reservoir Sampling.

1. Let $s$ be the selected element. Initially $s \leftarrow e_1$.
2. When $e_i$ arrives, set $s \leftarrow e_i$ with probability $\frac{1}{i}$.
3. When the stream ends, return $s$.

The space complexity of this algorithm is also $O(\log n + \log m)$ bits: $O(\log n)$ for storing the counter $i$, and $O(\log m)$ space for storing the chosen number $s$.

Lemma 1. In the reservoir sampling algorithm, $\Pr(s = e_i) = 1/n$ for every $e_i$ in the stream.

Proof. We have

\[
\Pr(s = e_i) = \Pr(s \leftarrow e_i \text{ and no other element is chosen as } s) \\
= \Pr(s \leftarrow e_i) \cdot \Pr(\text{no other element is chosen as } s) \quad \text{(because every step is independent)} \\
= \frac{1}{i} \cdot \Pr(\text{no other element is chosen}) \quad \text{(because we select } e_i \text{ as } s \text{ with probability } 1/i) \\
= \frac{1}{i} \cdot \prod_{j=i+1}^{n} (1 - \Pr(s \leftarrow e_j)) \quad \text{(again, because every step is independent)} \\
= \frac{1}{i} \cdot \prod_{j=i+1}^{n} \left(1 - \frac{1}{j}\right) \quad \text{(again, because we select } e_j \text{ as with probability } 1/j) \\
= \frac{1}{i} \cdot \prod_{j=i+1}^{n} \frac{j - 1}{j} = \frac{1}{i} \cdot \frac{i}{i+1} \cdot \frac{i+1}{i+2} \cdots \frac{n-1}{n} = \frac{1}{n},
\]

concluding the proof.

We leave it as an easy exercise to the reader to show how one can modify this algorithm to sample $k$ numbers from the stream (both with or without repetition) in $O(k \cdot (\log n + \log m))$ space.

An interesting question? The $O(\log m)$ space in the algorithm is clearly necessary just to output the answer. But what about the $\log n$ term? Can one prove that if we are required to output a number truly uniformly at random\(^1\) from $n$ numbers we also need the extra $O(\log n)$ factor in the space?

\(^1\)As opposed to sample each element with probability, say, $\frac{1 \pm o(1)}{n}$.
1.3 Distinct Element Counting

We now consider one of the first (and highly influential) problems considered in the streaming model, namely, the distinct element (counting) problem.

**Problem 2.** Given a stream of $n$ elements from the universe $[m]$, output the number of distinct elements in the stream, denoted by $DE$.

For example, if $m = 5$, and the stream is $1, 2, 2, 1, 5, 4, 2, 2, 1$, then the answer is $DE = 4$.

There are two naive solutions to this problem:

- Store the entire universe: Use a bitmap with $m$ bits. Every time we see a new element, mark it. This requires $O(m)$ bits.
- Store the entire stream: Store a set of all the elements we receive. This requires $O(n \log m)$ bits.

These type of straightforward solutions are applicable to most streaming problems.

What about an algorithm using poly($\log n, \log m$) bits? In the next lecture we will show that this is not possible without randomization and approximation, by proving the following lower bounds:

- Every deterministic algorithm requires $\Omega(m)$ bits, even if it is a, say, 1.1-approximation.
- Every exact randomized algorithm requires $\Omega(n)$ bits.

Therefore, to find a sublinear space streaming algorithm we need to allow for both approximation and randomization. In particular, we require our algorithm to output a number $\tilde{DE}$ such that

$$\Pr \left( |DE - \tilde{DE}| \leq \varepsilon \cdot DE \right) \geq 1 - \delta.$$ 

In the next two sections of this lecture, we will give two algorithms that solve this problem using

$$\text{poly}(\log n, \log m, 1/\varepsilon, \log(1/\delta))$$

bits of space, which is much more efficient than the naive approaches above.

2 A Geometric Search Algorithm

Our first algorithm will use a standard and highly useful trick. The idea is to introduce a variable $T$, that takes values in $[m]$, and for each $T$ decide whether $DE$ is approximately smaller or larger than $T$. More specifically,

**Problem 3.** Design a randomized streaming algorithm $A$, that given a threshold $T$, and a stream of $n$ numbers from $[m]$:

- if $DE \leq T$, $A$ answers No with probability $\geq 1 - \delta$;
- if $DE > 2T$, $A$ answers Yes with probability $\geq 1 - \delta$.

We will refer to $A$ as an algorithm to (threshold) test $DE$. Assuming $A$ answers correctly most of the time, the sequence of outputs over an increasing sequence of thresholds will be roughly bitonic, and the stationary point will be approximately $DE$. Since $A$ is not committed to a specific output when $DE \in (T, 2T]$, its answer when the threshold is near $DE$ can go either way. See Figure 1.
Before we solve this threshold version of the problem, we show how to use such an algorithm to construct an approximation algorithm for the original problem.

2.1 From Threshold Testing to Solving the Original Problem

Consider the following generic algorithm for going from threshold testing of distinct element problem to the original approximation version.

**Algorithm:**

1. For each $i \in \{0, \ldots, \log m\}$, let $T_i := 2^i$.
2. Let $\mathcal{A}$ be a randomized streaming algorithm for testing $\text{DE}$.
3. Run $\mathcal{A}$ for each of the $T_i$’s (in parallel) with confidence parameter $\delta' = \delta / (2 \log m)$.
4. Starting from $i = 0$ to $\log m$, let $\widetilde{\text{DE}}$ be the first $T_i$ that $\mathcal{A}$ answered No on $T_i$. Return $\widetilde{\text{DE}}$.

The space complexity of this algorithm is $O(\log m)$ times the space complexity of $\mathcal{A}$ (for confidence parameter $\delta = O(\delta / \log m)$). So if we design a small-space algorithm $\mathcal{A}$ for the threshold version of the problem, we will also obtain a small-space algorithm for the original problem to within poly log($m$) factors.

**Lemma 2.** The algorithm outputs a 2-approximation of $\text{DE}$ with probability at least $1 - \delta$.

**Proof.** Let $i$ be the integer such that $T_i \leq \text{DE} < T_{i+1}$. We argue that the algorithm will output one of $\{T_i, T_{i+1}\}$ with probability $1 - \delta$ which will be a 2-approximation by definition.

Consider the events:

- $\mathcal{E}_1$: when $\widetilde{\text{DE}} \leq T_{i-1}$; and,
- $\mathcal{E}_2$: when $\widetilde{\text{DE}} \geq T_{i+2}$.

Then, $\Pr(\widetilde{\text{DE}} \notin \{T_i, T_{i+1}\}) = \Pr(\mathcal{E}_1 \cup \mathcal{E}_2) = \Pr(\mathcal{E}_1) + \Pr(\mathcal{E}_2)$. On the one hand,

$$
\Pr(\mathcal{E}_1) = \Pr(\mathcal{A} \text{ answers No for some } T_j, \text{ with } j \leq i - 1) \\
\leq \sum_{j=0}^{i-1} \Pr(\mathcal{A} \text{ answers No for } T_j) \quad \text{(by union bound)} \\
\leq \sum_{j=0}^{i-1} \frac{\delta}{2 \log m} \quad \text{(because } \text{DE} > 2 \cdot T_j \text{ and the probability that } \mathcal{A} \text{ errs is at most } \delta / (2 \log m)) \\
\leq \log m \cdot \frac{\delta}{2 \log m} = \frac{\delta}{2}.
$$
On the other hand,

\[ \Pr(\mathcal{E}_2) = \Pr(\mathcal{A} \text{ answers } \text{Yes for all } T_j \text{ with } j \leq i + 1) \]
\[ \leq \Pr(\mathcal{A} \text{ answers } \text{Yes for } T_{i+1}) \]
\[ \leq \frac{\delta}{2 \log m}. \]  
(because \( \mathcal{DE} < T_{i+1} \) and the probability that \( \mathcal{A} \text{ errs} \) is \( \delta/(2 \log m) \))

Thus

\[ \Pr(\tilde{\mathcal{DE}} \notin \{T_i, T_{i+1}\}) \leq \delta/2 + \delta/2 \log m \leq \delta, \]
as desired. This concludes the proof.

**Remark.** The approximation factor 2 in this algorithm can be improved to \( 1 + \varepsilon \) for any \( \varepsilon > 0 \), by reducing the geometric ratio of the thresholds to \( 1 + \varepsilon \), and solving the threshold version of the problem for distinguishing between \( T \) and \( (1 + \varepsilon) \cdot T \). We omit the details as we are going to see a more space-efficient algorithm for this task anyway.

**Remark.** Notice that our algorithm in this section (and in particular Lemma 2) did not use any details of \( \mathcal{A} \) (i.e., treated it as a black-box) or for that matter even any particular knowledge the problem at hand, namely, estimating \( \mathcal{DE} \). As such, this trick of combining a threshold-testing version of a problem with geometric searching can be applied to other problems as well and forms a standard technique in streaming algorithms (as well as many other algorithms).

### 2.2 An Algorithm for Threshold Testing \( \mathcal{DE} \)

The following algorithm solves the threshold testing problem, for a given threshold \( T \). We may assume that \( T \geq 100 \), since for any \( T = O(1) \) we can simply use the deterministic \( O(T \log m) \)-space naive algorithm that stores all the distinct elements it sees and answers \( \text{Yes} \) as soon as it sees \( T + 1 \) of them.

**Algorithm:** A preliminary version of the threshold testing algorithm \( \mathcal{A} \).

1. Pick a truly random hash function \( h : [m] \rightarrow [T] \) (i.e., each element in \([m]\) is hashed independently to some number in \([T]\) chosen uniformly at random).
2. For each element in the stream, check \( h(e_i) \). If \( h(e_i) = 1 \), return \( \text{Yes} \).
3. If the stream ends, return \( \text{No} \).

We will consider the space complexity of this algorithm later in the section. For now, we should only note that as it is, this algorithm requires prohibitively large space to store the hash function \( h \) and hence is not space-efficient. Regardless, it forms the main building block for our final algorithm and thus we focus on proving its correctness in the following.

The intuition behind the algorithm is as follows: for each *distinct* number in the stream, \( h(\cdot) \) has a chance of hitting 1 with probability \( 1/T \). As such, if \( \mathcal{DE} > 2T \), then it is very likely that one of the values will be hashed to 1, but if \( \mathcal{DE} \leq T \) that probability is lower.

Although we need \( \mathcal{A} \) to answer correctly with confidence \( 1 - \delta \), this algorithm, as is, does not quite get us that far. We will first prove that \( \mathcal{A} \) answers correctly with constant nonzero probability, and then show how to boost that probability to \( 1 - \delta \).
Lemma 3. The following two are true for $A$:

- if $DE \leq T$, then $A$ answers No with probability $\geq 1/e^{1.01}$;
- if $DE > 2T$, then $A$ answers No with probability $\leq 1/e^2$.

Proof. Let $i_1, \ldots, i_{DE} \in [n]$ be the indices of the distinct elements of the stream. If $DE > 2T$, then

$$\Pr(A \text{ answers } No) = \Pr(h(e_j) \neq 1 \text{ for all } j \in [DE])$$

$$= \prod_{j=1}^{DE} \Pr(h(e_j) \neq 1) \quad \text{(because } h \text{ is truly random and thus independent for each } e_j)$$

$$= \prod_{j=1}^{DE} \left(1 - \frac{1}{T}\right)^{DE}$$

$$= \left(1 - \frac{1}{T}\right)^{DE}$$

$$\leq \exp(-DE/T) \quad \text{(by the inequality } 1 - x \leq e^{-x} \text{ for all } x)$$

$$< \frac{1}{e^2}. \quad \text{(as } DE > 2T)$$

Now suppose $DE \leq T$. Just as in the previous case, we have

$$\Pr(A \text{ answers } No) = \left(1 - \frac{1}{T}\right)^{DE}.$$  

In this case, this is the probability that $A$ gives the right answer, so we want a lower bound. We use the following upper bound for the exponential function to simplify the above bound.

Proposition 4. Let $c > 1$ be any real number. Then $e^{-cx} \leq 1 - x$ for all $x \in [0, \min\{\frac{1}{c}, 2 \cdot \frac{c-1}{c^2}\}]$.

Proof. The inequality is trivial for $x = 0$. Let $x > 0$. Consider the Taylor series for $e^{-cx}$:

$$e^{-cx} = 1 - cx + \frac{(cx)^2}{2!} - \frac{(cx)^3}{3!} + \ldots$$

This is an alternating series in which the terms are monotonically decreasing in absolute value, since

$$\frac{(cx)^i}{i!} \geq \frac{(cx)^{i+1}}{(i+1)!} \iff \frac{(cx)^{i+1}}{(cx)^i} \geq \frac{(i+1)!}{i!} \iff \frac{i+1}{c} \geq x,$$

and the last inequality holds because $x \leq 1/c$. Thus, we can bound the series by any partial sum up to any positive term. In particular,

$$e^{-cx} \leq 1 - cx + \frac{(cx)^2}{2}.$$  

An easy calculation shows that $1 - cx + \frac{(cx)^2}{2} \leq 1 - x$ if and only if $x \leq 2 \cdot \frac{1}{c^2}$.

By setting $c = 1.01$ in Proposition 4, we have $1 - x \geq e^{-1.01x}$ for all $x \in [0, 0.01]$. Since $T \geq 100$, then $1/T \leq 0.01$, and thus the inequality implies that $1 - 1/T \geq \exp(-1.01/T)$. Therefore,

$$\Pr(A \text{ answers } No) \geq \exp(-1.01 \frac{DE}{T}) \geq 1/e^{1.01}, \quad \text{(since } DE \leq T)$$

concluding the proof.
Lemma 3 implies that we “expect” to see No more often when $DE \leq T$ compared to when $DE > 2T$. However, these probabilities are still far from our desired bounds of $\delta$ on the error (or even, say, $(1/3)$-error).

We are already familiar with the concept of amplifying probability of success from previous lectures. For instance, we have previously used independent repetition of one-sided error algorithms, and majority/median voting on algorithms with error probability “around” half. In the case of Lemma 3 however, $A$ is a two-sided error algorithm with error probabilities that are in both cases “far from” half. Nevertheless, the previous approaches can be adjusted for this purpose as well.

One way to amplify the confidence of algorithm in deciding whether $T \leq DE$ or $T > 2DE$, is to exploit the additive constant gap between the probability that $A$ answers No in each case. Paraphrasing Lemma 3, if $DE \leq T$, then at least $1/e^{1.01}$ of the time $A$ will output No, and if $DE > 2T$, then at most $1/e^2 < 1/e^{1.01} - 0.22$ of the time $A$ will output No. Thus, after running $A$ sufficiently many times, we can tell which case we are in. We do so using the following algorithm.

**Algorithm:** A final version of $A$ with the amplified probability of success.

1. Let $\lambda := \frac{1}{2} \cdot \left( \frac{1}{e^2} + \frac{1}{e^{1.01}} \right)$. Let $\lambda_1 := \lambda - 1/e^2$ and $\lambda_2 := 1/e^{1.01} - \lambda$.
2. Run $A$ for $k := \ln(\frac{2}{e}) \cdot \frac{1}{2} \cdot \max \left\{ \frac{1}{\lambda_1^2}, \frac{1}{\lambda_2^2} \right\}$ independent times, in parallel.
3. Let $N_i$ be the indicator variable that is 1 if and only if $A$ answers No in the $i$-th execution. Let $N := \sum_{i=1}^{k} N_i$.
4. If $N \geq \lambda \cdot k$, answer No; otherwise, answer Yes.

**Lemma 5.** Amplified $A$ returns the right answer with probability at least $1 - \delta$.

**Proof.** First suppose $DE \leq T$, so the right answer in this case is No. The confidence guarantee of $A$ when $DE \leq T$ implies $E[N_i] = \Pr(A \text{ answers } No) \geq 1/e^{1.01}$, and thus $E[N] \geq k/e^{1.01}$. We have

$$\Pr(\text{answer Yes}) = \Pr(N < \lambda k) = \Pr \left( \frac{1}{e^{1.01}} - \lambda_2 \right) \leq \Pr \left( \frac{1}{e} - \lambda_2 \right) \leq 2 \cdot \exp \left( - \frac{2 \lambda_2^2 k^2}{k} \right) \leq \delta.$$  

The case $DE > 2T$ is symmetric.

As such, we can indeed amplify the success probability of original $A$ to within $1 - \delta$ using $O(\ln(1/\delta))$ independent repetitions in parallel. Note that in terms of a streaming algorithm, this only increases the space by a factor of $O(\ln(1/\delta))$ compared to the original algorithm. We also emphasize that all these copies are being run in parallel.

**Space complexity of $A$?** The algorithm we designed in this section is still not a space-efficient streaming algorithm – while the entire space of the algorithm throughout the stream is $O(\log m)$ to store $e_i$ and compute $h(e_i)$, storing the random bits in $h$ itself requires $O(m \log T)$ bits (which makes the space of the algorithm more than the naive $O(m)$ space!).

7
Sometimes, the only bottleneck in space of our algorithms is to store random bits. Previously, we mentioned that this is often not problematic and can be remedied through use of some “pseudo-random numbers” instead of truly random numbers. In the next section, we will examine one such option (used extensively in streaming algorithms) in details.

2.3 Trading Independence for Space: Limited-Independence Hash Functions

Generating and storing a random function \( h : [m] \rightarrow [T] \) requires \( O(m \log T) \) bits, which is often too costly. Although the analysis of \( \mathcal{A} \) relies on the full independence provided by the random hash function, we can make it work even when there is only “limited independence” in this hash function. Let us define this formally as follows.

**Definition 6.** A family \( \mathcal{H} = \{ h : [a] \rightarrow [b] \} \) is called a k-wise independent family of hash functions if for all pairwise distinct \( x_1, \ldots, x_k \in [a] \) and all \( y_1, \ldots, y_k \in [b] \),

\[
\Pr_{h \sim \mathcal{H}} (h(x_1) = y_1 \wedge \cdots \wedge h(x_k) = y_k) = \frac{1}{b^k}.
\]

Observe that a k-wise independent family may also be \((k+1)\)-wise independent, i.e., the definition does not necessarily break for \( k+1 \) hash values (although for “interesting” families this is almost always the case). For instance, a truly random hash function is \( k \)-wise independent for all \( k \).

**Proposition 7.** Let \( \mathcal{H} = \{ h : [a] \rightarrow [b] \} \) be a \( k \)-wise independent, and \( h \sim \mathcal{H} \) chosen at random. Let \( x_1, \ldots, x_k \in [a] \) be arbitrary pairwise distinct elements. Then:

1. for every \( i \in [k] \), \( h(x_i) \) is uniform over \([b]\);
2. \( h(x_1), \ldots, h(x_k) \) are mutually independent.

**Proof.** We prove each part separately.

1. We only prove this for \( i = 1 \); the rest is symmetric. Let \( y_1 \in [b] \). Observe that

\[
\Pr_{h \sim \mathcal{H}} (h(x_1) = y_1) = \sum_{y_2, \ldots, y_k \in [b]} \Pr_{h \sim \mathcal{H}} (h(x_1) = y_1 \wedge h(x_2) = y_2 \wedge \cdots \wedge h(x_k) = y_k)
\]

(partitioning the sample space)

\[
= \sum_{y_2, \ldots, y_k \in [b]} \frac{1}{b^k} = \frac{b^{k-1}}{b^k} = \frac{1}{b}.
\]

(by definition of k-wise independent family)

2. Let \( y_1, \ldots, y_k \in [b] \). Since all \( h(x_i) \) are uniform over \([b]\), it follows that

\[
\Pr_{h \sim \mathcal{H}} (h(x_1) = y_1 \wedge \cdots \wedge h(x_k) = y_k) = \frac{1}{b^k} = \prod_{i=1}^{k} \Pr_{h \sim \mathcal{H}} (h(x_i) = y_i).
\]

This concludes the proof.

**Example.** Let \( k \geq 2 \) be an integer and \( p > k \) be a prime number. Here is an example of a \( k \)-wise independent family of hash functions mapping \([p] \rightarrow [p] \).
**k-wise Independent Family of Hash Functions:**

1. $\mathcal{H}$ is the set of degree-$(k-1)$ polynomial functions over $\mathbb{F}_p$ (field of integers mod prime $p$). That is, $\mathcal{H} = \{ h : [p] \to [p] \ | \ h(x) = c_{k-1}x^{k-1} + c_{k-2}x^{k-2} + \cdots + c_1x + c_0, \text{ with } c_0, \ldots, c_{k-1} \in \mathbb{F}_p \}$.

2. Sampling $h \sim \mathcal{H}$: Sample $c_0, \ldots, c_{k-1} \in \mathbb{F}_p$. Then $h$ is the polynomial defined by this coefficients.

To see why this is a $k$-wise independent hash function, note that any degree-$(k-1)$ polynomial $h$ is uniquely determined by having $k$ of its values (i.e., $k$ distinct $(x, h(x))$ pairs for $x \in \mathbb{F}_p$): if we fix only $k-1$ values of $h$ on $x_1, \ldots, x_{k-1}$, value of $h(x_k)$ for any other $x_k$ is still chosen uniformly at random from $\mathbb{F}_p$ (we omit the simple algebraic proof of this statement as it is not the focus of this lecture).

The important thing we would like to note about the family $\mathcal{H}$ is on how much space we need to store $h$. Since each function in the family is defined by $k$ polynomial coefficients, the space required to generate and store it is only $O(k \log p)$ bits (as opposed to $O(p \log p)$ for a truly random hash function mapping $[p] \to [p]$).

It is also possible to evaluate any such hash function in the same amount of space.

Although this family only works for $a = b = p$, we can in general construct families for arbitrary $a$ and $b$.

**Proposition 8.** For any $a, b$, there exists a $k$-wise independent family of hash functions mapping $[a] \to [b]$, that requires $O(k \cdot (\log a + \log b))$ bits.

**Remark.** We can replace the truly random hash function $h : [m] \to [T]$ in algorithm of previous section with a 2-wise independent hash function that only requires $O(\log m + \log T) = O(\log m)$ bits to store. Using a slightly different analysis, one can then prove that the algorithm continues to output the correct answer with sufficiently large probability. This way we can obtain a streaming algorithm for the threshold testing problem using $O(\log m \cdot \log (1/\delta))$ space. By combining this with the geometric search algorithm, we get an algorithm for 2-approximation of $DE$ using $O(\log^2 m \cdot (\log \log m + \log (1/\delta)))$ space. In the next section, we give a simpler and more direct algorithm for this problem.

### 3 A Better Algorithm for Estimating $DE$

To improve the space cost and achieve a $(1 + \varepsilon)$-approximation to $DE$, we will combine the idea of limiting the independency with a more direct algorithm.

The intuition is as follows: Suppose every time we receive a number from the universe $[m]$, we hash it to one of $m$ slots. To simplify things, suppose there are no collisions. At the end of the stream, $DE$ slots will be non-empty and we “expect” them to be evenly distributed – the first nonempty slot should be approximately at $m/DE$, the second at $2 \cdot m/DE$, and the $t$-th one at $t \cdot m/DE$. Thus, if we can compute the $t$-th nonempty slot number $X$, we can use $X \approx t \cdot m/DE$ to estimate $DE$ (the reason we go for some relatively larger $t$ as opposed to just $t = 1$ is to make the concentration results in the algorithm work as it will become evident).

**Algorithm:** The main streaming algorithm for estimating $DE$.

1. Let $\mathcal{H}$ be a 2-wise independent family of hash functions mapping $[m] \to [m]$. Pick $h \in \mathcal{H}$ at random.

2. Let $t := 100/\varepsilon^2$. Maintain the $t$ smallest pairs $(e_i, h(e_i))$ ordered by the hash value, breaking ties consistently but arbitrarily (note that we do not keep $(e_i, \star)$ more than once).

3. Let $X$ be the $t$-th smallest hash value among the pairs.

4. Return $\overline{DE} := t \cdot m/X$. 
By Proposition 8, we can generate and store \( h \) in \( O(\log m) \) bits. Maintaining the \( t \) smallest pairs requires \( O(t \cdot \log m) \) bits. Therefore, the algorithm uses \( O(t \cdot \log m) = O(1/\varepsilon^2 \cdot \log m) \) bits.

Observe that the algorithm does not simply take \( t = 1 \), i.e., estimating via the minimum hash value. This is because the minimum yields higher variance than the \( t \)-th smallest, for \( t > 1 \), as the proof will reveal. Another characteristic of this algorithm is that, unlike most other algorithms we have seen so far in the course, it does not compute an unbiased estimator of the target \( \Delta E \), as \( \mathbb{E} [\Delta E] \neq \Delta E \).\(^2\) We now prove the correctness of the algorithm.

**Lemma 9.** In the algorithm above, \( \Pr \left( |\Delta E - \Delta E| > \varepsilon \cdot \Delta E \right) \leq \frac{1}{10} \).

**Proof.** We will bound the upper and lower tails separately. For the lower tail, we have

\[
\Pr \left( \Delta E < (1 - \varepsilon) \cdot \Delta E \right) = \Pr \left( t \cdot m / X < (1 - \varepsilon) \cdot \Delta E \right)
= \Pr \left( X > \frac{t \cdot m}{(1 - \varepsilon) \cdot \Delta E} \right)
= \Pr \left( \text{less than } t \text{ distinct elements hash to a value} \leq \frac{t \cdot m}{(1 - \varepsilon) \cdot \Delta E} \right); \tag{1}
\]

The last equation holds because the only way for \( X \), i.e., the value of \( t \)-th smallest hash-value in the stream, to be larger than some threshold \( \tau := \frac{t \cdot m}{(1 - \varepsilon) \cdot \Delta E} \), is that less than \( t \) numbers are hashed to \([1 : \tau]\).

For each \( i \in [\Delta E] \), define the indicator variable \( Y_i \) that is 1 if the \( i \)-th distinct number seen in the stream hashes to a value \( < \tau \), and 0 otherwise. Let \( Y := \sum_{i=1}^{\Delta E} Y_i \). Since elements are hashed uniformly,

\[
\mathbb{E}[Y_i] = \frac{t \cdot m}{(1 - \varepsilon) \cdot \Delta E} \cdot \frac{1}{m} = \frac{t}{(1 - \varepsilon) \cdot \Delta E},
\]

and therefore \( \mathbb{E}[Y] = \frac{t}{(1 - \varepsilon)} \). We can rewrite the probability of Eq (1) in terms of \( Y \) simply as \( \Pr (Y < t) \):

\[
\Pr \left( \Delta E < (1 - \varepsilon) \cdot \Delta E \right) = \Pr (Y < t)
= \Pr (Y < (1 - \varepsilon) \cdot \mathbb{E}[Y]) \tag{since \( \mathbb{E}[Y] = \frac{t}{(1 - \varepsilon)} \))
\leq \Pr \left( |Y - \mathbb{E}[Y]| \leq \varepsilon \mathbb{E}[Y] \right). \tag{2}
\]

Next we use a concentration bound on \( Y \). Although \( Y \) is a sum of 0-1 random variables, we cannot use Chernoff bounds because our hash function \( h \) is only 2-wise independent, and thus the \( Y_i \)'s are not mutually independent.\(^3\) Instead, we can bound the variance and use Chebyshev’s inequality. Recall that the variance is not linear in general, but it is if the variables are pairwise independent. Since \( h \) is 2-wise independent, it is easy to see that \( Y_1, \ldots, Y_{\Delta E} \) are pairwise independent. Thus,

\[
\mathbb{Var}[Y] = \mathbb{Var}\left[ \sum_{i=1}^{\Delta E} Y_i \right] = \sum_{i=1}^{\Delta E} \mathbb{Var}[Y_i] \tag{since \( Y_i \)'s are 2-wise independent}
\leq \sum_{i=1}^{\Delta E} \mathbb{E}[Y_i^2] = \sum_{i=1}^{\Delta E} \mathbb{E}[Y_i] = \mathbb{E}[Y]. \tag{since \( Y_i \)'s are indicator random variables and so \( Y_i^2 = Y_i \))
\]

Using Chebyshev’s inequality in Eq (2) yields

\[
\Pr \left( |Y - \mathbb{E}[Y]| \leq \varepsilon \mathbb{E}[Y] \right) \leq \frac{\mathbb{Var}[Y]}{\varepsilon^2 \mathbb{E}[Y]} \leq \frac{\mathbb{E}[Y]}{\varepsilon^2 \mathbb{E}[Y]^2} = \frac{1}{\varepsilon^2 t} \leq \frac{1}{\varepsilon^2 t} = \frac{1}{100},
\]

\(^2\)Recall that \( \mathbb{E} \left[ \frac{1}{X} \right] \neq \frac{1}{\mathbb{E}[X]} \) in general.

\(^3\)Although in this course we have only used Chernoff bounds that assume full independence, there are weaker variants that only require limited independence. Nevertheless, for our application it is easier (and sufficient) to simply use Chebyshev inequality instead.
by the choice of $t$. As such, we conclude that $\Pr \left( \widetilde{DE} < (1 - \varepsilon) \cdot DE \right) \leq 1/100$.

For the upper tail, we can bound $\Pr \left( \widetilde{DE} > (1 + \varepsilon) \cdot DE \right)$ symmetrically\(^4\). Finally, by union bound, we have

$$\Pr \left( |\widetilde{DE} - DE| > \varepsilon \cdot DE \right) \leq 1/50,$$

concluding the proof. \qed

As always, we can run this algorithm $O(\ln (1/\delta))$ times, in parallel, and then pick the median to boost the probability of success up to $1 - \delta$. This leads to the following theorem.

**Theorem 10.** There is a streaming algorithm that outputs a $(1 \pm \varepsilon)$-estimation of the number of distinct elements $DE$ from a universe $[m]$ with probability at least $1 - \delta$, using $O(\frac{1}{\varepsilon^2} \cdot \log m \cdot \log(1/\delta))$ bits of space.

The distinct element problem was first studied by Flajolet and Martin in [FM83] (long before the formalization of the streaming model). This problem was revisited in the work of Alon, Matias, and Szegedy [AMS96] that pioneered the streaming model. The algorithm we discussed in this section was proposed by Bar-Yossef, Jayram, Kumar, Sivakumar, and Trevisan [BJK+02] and was later improved in a series of work, culminating in the optimal algorithm of Kane, Nelson, and Woodruff [KNW10] with space complexity $O(\frac{1}{\varepsilon^2} + \log m)$.
